PAPER

How to select predictive models for decision-making or causal inference?

Matthieu Doutreligne[1,*] and Gaël Varoquaux[2]

Abstract

Background: We investigate which procedure selects the predictive model most trustworthy to reason on the effect of an intervention and support decision making.
Methods: We study such a variety of model selection procedures in practical settings: finite samples settings and without theoretical assumption of *well-specified* models. Beyond standard cross-validation or internal validation procedures, we also study elaborate causal risks. These build proxies of the causal error using "nuisance" re-weighting to compute it on the observed data. We evaluate whether empirically estimated nuisances, which are necessarily noisy, add noise to model selection. We compare different metrics for causal model selection in an extensive empirical study based on a simulation and three healthcare datasets based on real covariates.
Results: Among all metrics, the mean squared error, classically used to evaluate predictive modes, is worse. Re-weighting it with propensity score does not bring much improvements. The *R*-risk, which uses as nuisances a model of mean outcome and propensity scores, leads to the best performances. Nuisance corrections are best estimated with flexible estimators such as a super learner.
Conclusions: When predictive models are used to reason on the effect of an intervention, they must be evaluated with different procedures than standard predictive settings; using the *R*-risk from causal inference.

Key words: Model Selection, Predictive model, Treatment Effect, G-formula, Machine Learning

Introduction

Extending prediction to prescription needs causality

Prediction models have long been used in biomedical settings, as with risk score or prognostic models [1, 2]. While these have historically been simple models on simple data, this is changing with progress in machine learning and richer medical data [3, 4]. Health predictions can now integrate medical images [5, 6, 7, 8, 9], patient records [10, 11, 12] or clinical notes [13, 14, 15]. Complex data is difficult to control and model, but these models are validated by verifying the accuracy of the prediction on left-out data [16, 17, 18]. Crucial to the clinical adoption of a model predicting a health outcome is that it "can support decisions about patient care" [19]. Precision medicine is about guiding decisions: *eg* will an individual benefit from an intervention such as surgery [20]? An estimate of the effect of the treatment can be obtained by contrasting model predictions with and without the treatment, but statistical validity requires causal inference [21, 22, 23].

Indeed, concluding on the effect of a treatment is a difficult causal-inference task, as it can be easily compromised by confounding: spurious associations between treatment allocation and baseline health, *e.g.* only prescribing a drug to mild cases [24, 25]. Predictive modeling bridges to causal inference theory under the name of *outcome models* (or G-computation, G-formula [26], Q-model [21], conditional mean regression [27]). Medical statistics and epidemiology have mostly used other causal-inference methods, modeling treatment assignment with propensity scores [28, 29, 30, 31]. Outcome modeling brings the benefit of going beyond average effects, estimating individualized or conditional average treatment effects (CATE), central to precision medicine. For this purpose, such methods are also invaluable for randomized trials [32, 33, 34].

Compiled on: June 14, 2024.
Draft manuscript prepared by the author.

Outcome-modeling methods, even when specifically designed for causal inference, are numerous: Bayesian Additive Regression Trees [35], Targeted Maximum Likelihood Estimation [36, 37], causal boosting [38], causal multivariate adaptive regression splines [38], random forests [39, 40], Meta-learners [41], R-learners [42], Doubly robust estimation [43]... The wide variety of methods raises the problem of selecting between different estimators based on the data at hand. Indeed, estimates of treatment effects can vary markedly across different predictive models [44, 45] (illustration in Appendix A.1).

Given complex health data, which predictive model is to be most trusted to yield valid causal estimates needed to motivate individual treatment decisions? As no single machine-learning method performs best across all data sets, there is a pressing need for clear guidelines to select outcome models for causal inference.

Objectives and structure of the paper. We study *model selection procedures* in practical settings, without theoretical assumptions often made in statistical literature such as *infinite* data or *well-specified* models (Appendix A.2). Asymptotic causal-inference theory recommends complex risks, but a practical question is whether model-selection procedures, that rely on data split, can estimate these risks reliably enough. Indeed, these risks come with more quantities to estimate, which may bring additional variance, leading to worse model selection.

We first illustrate the problem of causal model selection. Then we anchor causal model selection in the *potential outcome* framework and details the causal risks and model-selection procedure. We then rewrite the so-called R-risk as a reweighted version of mean squared difference between the true and estimated individualized treatment effect. Finally, we conduct a thorough empirical study comparing the different metrics on diverse datasets, using a family of simulations and real health data, going beyond prior work limited to specific simulation settings [46, 47] (Appendix A.2).

Illustration: the best predictor may not estimate best causal effects

Using a predictor to reason on causal effects relies on contrasting the prediction of the outcome for a given individual with and without the treatment. Given various predictors of the outcome, which one should we use? Standard predictive modeling or machine-learning practice selects the predictor that minimizes the expected error on the outcome [17, 18]. However, this predictor may not be the best model to reason about causal effects of an intervention as Figure 1 illustrates. Consider the probability Y of an undesirable outcome (*e.g.*death), a binary treatment $A \in \{0, 1\}$, and a covariate $X \in \mathbb{R}$ summarizing the patient health status (*e.g.*the Charlson index [48]). We simulate a treatment beneficial (decreases mortality) for patients with high Charlson scores (bad health status) but with little effect for patients in good condition (low Charlson scores).

Figure 1a shows a random forest predictor with a counter-intuitive behavior: it predicts well on average the outcome (as measured by a regression R^2 score) but perform poorly to estimate causal quantities: the average treatment effect τ (as visible via the error $|\tau - \hat{\tau}|$) or the conditional average treatment effect (the error $\mathbb{E}[(\tau(x) - \hat{\tau}(x))^2]$, called CATE). On the contrary, Figure 1b shows a linear model with smaller R^2 score but better causal inference.

The problem is that causal estimation requires controlling an error on both treated and non-treated outcome for the same individual: the observed outcome, and the non-observed *counterfactual* one. The linear model is misspecified –the outcome functions are not linear–, leading to poor R^2; but it interpolates better to regions where there are few untreated individuals –high Charlson score– and thus gives better causal estimates. Conversely, the random forest puts weaker assumptions on the data, thus has higher R^2 score but is biased by the treated population in the poor-overlap region, leading to bad causal estimates.

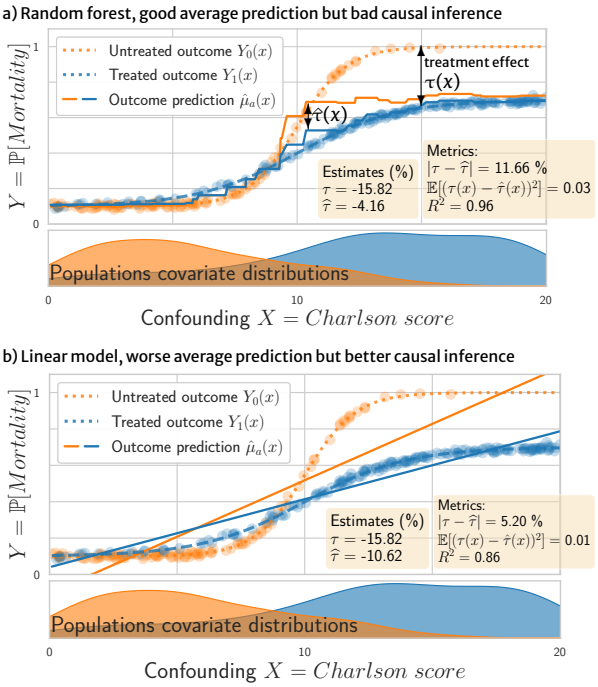

Figure 1. Illustration: a) a random-forest predictor with high performance for standard prediction (high R^2) but that yields poor causal estimates (large error between true effect τ and estimated $\hat{\tau}$), b) a linear predictor with smaller prediction performance leading to better causal estimation.

Selecting the predictor with the smallest error to the individual treatment effect $\mathbb{E}[(\tau(x) - \hat{\tau}(x))^2]$ –the τ-risk, eq. 9 – would lead to the best causal estimates; however computing this error is not feasible: it requires access to unknown quantities: $\tau(x)$.

While the random forest fits the data better than the linear model, it gives worse causal inference because its error is inhomogeneous between treated and untreated. The R^2 score does not capture this inhomogeneity.

This toy example illustrates that the classic minimum Mean Square Error criterion is not suited to choosing a model among candidate estimators for causal inference.

Methods

Neyman-Rubin Potential Outcomes framework

Settings. The Neyman-Rubin Potential Outcomes framework [49, 50] enables statistical reasoning on causal treatment effects: Given an outcome $Y \in \mathbb{R}$ (*e.g.*mortality risk or hospitalization length), function of a binary treatment $A \in \mathcal{A} = \{0, 1\}$ (*e.g.* a medical procedure), and baseline covariates $X \in \mathcal{X} \subset \mathbb{R}^d$, we observe the factual distribution, $O = (Y(A), X, A) \sim \mathcal{D} = \mathbb{P}(y, x, a)$. However, we want to model the existence of potential observations (unobserved ie. counterfactual) that correspond to a different treatment. Thus we want quantities on the counterfactual distribution $O^* = (Y(1), Y(0), X, A) \sim \mathcal{D}^* = \mathbb{P}(y(1), y(0), x, a)$.

Popular quantities of interest (estimands) are: at the population level, the Average Treatment Effect

$$\text{ATE} \qquad \tau \overset{\text{def}}{=} \mathbb{E}_{Y(1),Y(0)\sim\mathcal{D}^*}[Y(1) - Y(0)];$$

at the individual level, to model heterogeneity, the Conditional Average Treatment Effect

$$\text{CATE} \qquad \tau(x) \overset{\text{def}}{=} \mathbb{E}_{Y(1),Y(0)\sim\mathcal{D}^*}[Y(1) - Y(0)|X = x].$$

Causal assumptions. A given data needs to meet a few assumptions to enable identifying causal estimands [51]. The usual *strong ignorability* assumptions are (details in A.3): *1) unconfoundedness* $\{Y(0), Y(1)\} \perp\!\!\!\perp A|X$, *2) strong overlap* ie. every patient has a strictly positive probability to receive each treatment, *3) consistency*, and *4) generalization*.

Estimating treatment effects with outcome models – g-computation [52]. Should we know the two expected outcomes for a given X, we could compute the difference between them, which gives the causal effect of the treatment. These two expected outcomes can be estimated from observed data: the consistency 3 and unconfoundedness 1 assumptions imply the following equality:

$$\mathbb{E}_{Y(a)\sim\mathcal{D}^\star}[Y(a)|X = x] = \mathbb{E}_{Y\sim\mathcal{D}}[Y|X = x, A = a] \tag{1}$$

On the left, the expectation is taken on the counterfactual unobserved distribution. On the right, the expectation is taken on the factual observed distribution conditionally on the treatment. For the rest of the paper, the expectations will always be taken on the factual observed distribution $\mathcal{D}$. This identification leads to outcome based estimators (ie. g-computation estimators [21]):

$$\begin{aligned}\tau &= \mathbb{E}_{Y\sim\mathcal{D}^\star}[Y(1) - Y(0)|X = x] \\ &= \mathbb{E}_{Y\sim\mathcal{D}}[Y|A = 1] - \mathbb{E}_{Y\sim\mathcal{D}}[Y|A = 0]\end{aligned} \tag{2}$$

This equation builds on two quantities: the conditional expectancy of the outcome given the covariates and either treatment or no no treatment, called *response function*:

$$\text{Response function} \qquad \mu_a(x) \overset{\text{def}}{=} \mathbb{E}_{Y\sim\mathcal{D}}[Y|X = x, A = a]$$

Given a sample of data and the oracle response functions μ_0, μ_1, the finite sum version of Equation 2 leads to an estimator of the ATE written:

$$\hat{\tau} = \frac{1}{n}\left(\sum_{i=1}^{n} \mu_1(x_i) - \mu_0(x_i)\right) \tag{3}$$

This estimator is an oracle *finite sum* estimator by opposition to the population expression of τ, $\mathbb{E}[\mu_1(x_i) - \mu_0(x_i)]$, which involves an expectation taken on the full distribution $\mathcal{D}$, which is observable but requires infinite data. For each estimator ℓ taking an expectation over $\mathcal{D}$, we use the symbol $\hat{\ell}$ to note its finite sum version.

Similarly to the ATE, at the individual level, the CATE:

$$\tau(x) = \mu_1(x) - \mu_0(x) \tag{4}$$

Robinson decomposition. The *R-decomposition* of the outcome model[53] plays an important role: introducing two quantities, the conditional mean outcome and the probability to be treated (known as propensity score [28]):

$$\text{Conditional mean outcome} \qquad m(x) \overset{\text{def}}{=} \mathbb{E}_{Y\sim\mathcal{D}}[Y|X = x] \tag{5}$$

$$\text{Propensity score} \qquad e(x) \overset{\text{def}}{=} \mathbb{P}[A = 1|X = x] \tag{6}$$

the outcome can be written

$$\text{R-decomposition} \qquad \begin{aligned} y(a) &= m(x) + (a - e(x))\tau(x) + \varepsilon(x;a) \\ &\text{with} \quad \mathbb{E}[\varepsilon(X;A)|X,A] = 0 \end{aligned} \tag{7}$$

m and e are often called *nuisances* [43]; they are unknown.

Model-selection risks, oracle and feasible

Causal model selection. We formalize model selection for causal estimation. Thanks to the g-formula identification (Equation 1), a given outcome model $f : \mathcal{X} \times \mathcal{A} \to \mathcal{Y}$ –learned from data or built from domain knowledge– induces feasible estimates of the ATE and CATE (eqs 3 and 4), $\hat{\tau}_f$ and $\hat{\tau}_f(x)$. Let $\mathcal{F} = \{f : \mathcal{X} \times \mathcal{A} \to \mathcal{Y}\}$ be a family of such estimators. Our goal is to select the best candidate in this family for the observed dataset O using a risk ℓ:

$$f_\ell^* = \underset{f\in\mathcal{F}}{\operatorname{argmin}}\, \ell(f, O) \tag{8}$$

We now detail possible risks ℓ, risks useful for causal model selection, and how to compute them.

The τ-risk: an oracle error risk. As we would like to target the CATE, the following evaluation risk is natural (also called PEHE [55, 35]):

$$\tau\text{-risk}(f) \overset{\text{def}}{=} \mathbb{E}_{X\sim p(X)}[(\tau(X) - \hat{\tau}_f(X))^2] \tag{9}$$

Given observed data from $p(X)$, the expectation is computed with a finite sum, as in eq. 3, to give an estimated value $\widehat{\tau\text{-risk}}(f)$. However this risk is not feasible as the oracles $\tau(x)$ are not accessible with the observed data $(Y, X, A) \sim \mathcal{D}$.

Feasible error risks. Table 1 lists *feasible* risks (Detailed in Appendix A.4), based on the prediction error of the outcome model and *observable* quantities. These observable, called nuisances are e – propensity score, eq 6– and m –conditional mean outcome, eq 5. We give the definitions as *semi-oracles*, function of the true unknown nuisances, but later instantiate them with estimated nuisances, noted $(\check{e}, \check{m})$. Semi-oracles risks are superscripted with the * symbol.

Estimation and model selection procedure

Causal model selection (eq 8) may involve estimating various quantities from the observed data: the outcome model f, its induced risk as introduce in the previous section, and possibly nuisances required by the risk. Given a dataset with N samples, we split out a train and a test sets $(\mathcal{T}, \mathcal{S})$. We fit each candidate estimator $f \in \mathcal{F}$ on $\mathcal{T}$. We also fit the nuisance models $(\check{e}, \check{m})$ on the train set $\mathcal{T}$, setting hyperparameters by a nested cross-validation before fitting the nuisance estimators with these parameters on the full train set. Causal quantities are then computed by applying the fitted candidates estimators $f \in \mathcal{F}$ on the test set $\mathcal{S}$. Finally, we compute the model-selection metrics for each candidate model on the test set. This procedure is described in Algorithm 1 and Figure 2.

Algorithm 1 Model selection procedure

Given train and test sets $(\mathcal{T}, \mathcal{S}) \sim \mathcal{D}$, a candidate estimators f, a causal metrics ℓ:

i. Prefit: Learn estimators for unknown nuisance quantities $(\check{e}, \check{m})$ on the training set $\mathcal{T}$
ii. Fit: learn $\hat{f}(\cdot, a)$ on $\mathcal{T}$
iii. Model selection: $\forall x \in \mathcal{S}$ predict $(\hat{f}(x, 1), \hat{f}(x, 0))$ and evaluate the estimator storing the metric value: $\ell(f, \mathcal{S})$ – possibly function of $\check{e}$ and $\check{m}$

Table 1. Review of causal risks — The R-risk* is called τ-risk$_R$ in [46].

Risk	Equation	Reference
τ-risk = MSE$(\tau(X), \tau_f(X))$	$\mathbb{E}_{X\sim p(X)}[(\tau(X) - \hat{\tau}_f(X))^2]$	Eq. 9 [35]
μ-risk = MSE$(Y, f(X))$	$\mathbb{E}_{(Y,X,A)\sim\mathcal{D}}\left[(Y - f(X;A))^2\right]$	Def. 1 [46]
μ-risk$^*_{IPW}$	$\mathbb{E}_{(Y,X,A)\sim\mathcal{D}}\left[\left(\frac{A}{e(X)} + \frac{1-A}{1-e(X)}\right)(Y - f(X;A))^2\right]$	Def. 2 [54]
τ-risk$^*_{IPW}$	$\mathbb{E}_{(Y,X,A)\sim\mathcal{D}}\left[\left(Y\left(\frac{A}{e(X)} - \frac{1-A}{1-e(X)}\right) - \hat{\tau}_f(X)\right)^2\right]$	Def. 3 [39]
U-risk*	$\mathbb{E}_{(Y,X,A)\sim\mathcal{D}}\left[\left(\frac{Y-m(X)}{A-e(X)} - \hat{\tau}_f(X)\right)^2\right]$	Def. 4 [42]
R-risk*	$\mathbb{E}_{(Y,X,A)\sim\mathcal{D}}\left[\left((Y - m(X)) - (A - e(X))\,\hat{\tau}_f(X)\right)^2\right]$	Def. 5 [42]

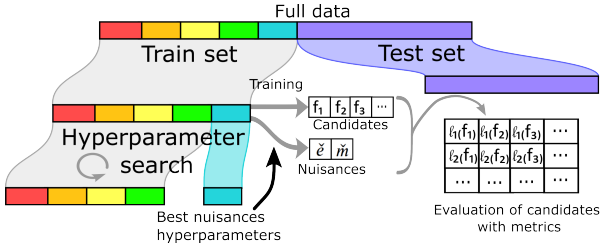

Figure 2. Estimation procedure for causal model selection.

R-risk as reweighted oracle metric

The R-risk can be rewritten as a rebalanced τ-risk.

This rewriting involves reweighted residuals: for each potential outcome, $a \in \{0;1\}$, the variance conditionally on x is [56]:

$$\sigma^2_Y(x;a) \stackrel{\text{def}}{=} \int_y (y - \mu_a(x))^2\, p(y \mid x = x; A = a)\, dy$$

Integrating over the population, we get the Bayes squared error: $\sigma^2_B(a) = \int_{\mathcal{X}} \sigma^2_Y(x;a)p(x)dx$ and its propensity weighted version: $\tilde{\sigma}^2_B(a) = \int_{\mathcal{X}} \sigma^2_Y(x;a)\, p(x;a)\, dx$. In case of a purely deterministic link between the covariates, the treatment, and the outcome, these residual terms are null.

Proposition 1 (R-risk as reweighted τ-risk) *Given an outcome model f, its R-risk appears as weighted version of its τ-risk (Proof in A.5):*

$$R\text{-risk}^*(f) = \int_x e(x)(1 - e(x))\,(\tau(x) - \tau_f(x))^2 p(x)dx + \tilde{\sigma}^2_B(1) + \tilde{\sigma}^2_B(0) \tag{10}$$

The R-risk targets the oracle at the cost of an overlap reweighting and the addition of the reweighted Bayes residuals, which are independent of f. In good overlap regions the weights $e(x)(1 - e(x))$ are close to $\frac{1}{4}$, hence the R-risk is close to the desired gold-standard τ-risk. For randomized control trials, this weight is constant making the R-risk particularly suited for exploring heterogeneity (Appendix A.5)

Empirical Study

We evaluate the following causal metrics, oracle and feasible versions, presented in Table 1: $\widehat{\mu\text{-risk}^*_{IPW}}$, $\widehat{R\text{-risk}^*}$, $\widehat{U\text{-risk}^*}$, $\widehat{\tau\text{-risk}^*_{IPW}}$, $\widehat{\mu\text{-risk}}$, $\widehat{\mu\text{-risk}_{IPW}}$, $\widehat{R\text{-risk}}$, $\widehat{U\text{-risk}}$, $\widehat{\tau\text{-risk}_{IPW}}$. We benchmark the metrics in a variety of settings: many different simulated data generation processes and three semi-simulated datasets [1].

1 Scripts for the simulations and the selection procedure are available at https://github.com/soda-inria/caussim.

Caussim: Extensive simulation settings

Data Generation. We use simulated data, on which the ground-truth causal effect is known. Going beyond prior empirical studies of causal model selection [46, 47], we use many generative processes, which is needed to reach general conclusions (Appendix A.7).

We generate the response functions using random bases extension, a common method in biostatistics, *e.g.*functional regression with splines [57, 58]. By allowing the function to vary at specific knots, we control the complexity of the non-linear outcome models. We use random approximation of Radial Basis Function (RBF) kernels [59] to generate the outcome and treatment functions. RBF use the same process as polynomial splines but replace polynomial by Gaussian kernels. Unlike polynomial, Gaussian kernels have decreasing influences in the input space. This avoids unrealistic divergences of the functions at the ends of the feature space. We generate 1 000 datasets based on these functions, with random overlap parameters. Example shown in Figure 12 and details in A.7.

Family of candidate estimators. We test model selection across different candidate estimators that approximate imperfectly the data-generating process. To build such estimators, we first use a RBF expansion similar to that used for data generation. We choose two random knots and transform the raw data features with a Gaussian kernel. This step is referred as the featurization. Then, we fit a linear regression on these transformed features. We consider two ways of combining these steps for outcome model; we use common nomenclature [41, 60] to refer to these different meta-learners that differ on how they model, jointly or not, the treated and the non treated:

- SLearner: A single learner for both population, taking the treatment as a supplementary covariate.
- SftLearner: A single set of basis functions is sampled at random for both populations, leading to a given feature space used to model both the treated and controls, then two separate different regressors are fitted on this shared representation.
- TLearner: Two completely different learners for each population, hence separate feature representations and regressors.

For the regression step, we fit a Ridge regression on the transformed features with 6 different choices of the regularization parameter $\lambda \in [10^{-3}, 10^{-2}, 10^{-1}, 1, 10^1, 10^2]$, coupled with a TLearner or a SftLearner. We sample 10 different random basis for learning and featurization yielding a family $\mathcal{F}$ of 120 candidate estimators.

Semi-simulated datasets

Datasets. We also use three semi-simulated data adding a known synthetic causal effect to real –non synthetic– healthcare covariate. ACIC 2016 [45] is based on the Collaborative Perinatal Project [61], a RCT studying infants' developmental disorders containing 4,802 indivduals and 55 features. We used 770 dataset instances: 10 random seeds for each of the 77 simulated settings for the treatment and outcomes. ACIC 2018 [62] simulated treatment and outcomes for the Linked Births and Infant Deaths Database (LBIDD) [63] with

$D = 177$ covariates. We used all 432 datasets of size $N = 5\,000$. Twins [64] is an augmentation of real data on twin births and mortality rates [65]. There are $N = 11\,984$ samples, and $D = 50$ covariates for which we simulated 1,000 different treatment allocations. Appendix A.7 gives datasets details.

Family of candidate estimators. For these three datasets, the family of candidate estimators are gradient boosting trees for both the response surfaces and the treatment [2] with S-learner, learning rate in $\{0.01, 0.1, 1\}$, and maximum number of leaf nodes in $\{25, 27, 30, 32, 35, 40\}$ resulting in a family of size 18.

Nuisance estimators. Drawing from the TMLE literature that uses combination of flexible machine learning methods [37], we model the nuisances $\check{e}$ (respectivley $\check{m}$) with a meta-learner: a stacked estimator of ridge and boosting classifiers (respectively regressions) (hyperparameter selection in Appendix A.7).

Measuring overlap between treated and non treated

Good overlap between treated and control population is crucial for causal inference (Assumption 2). We introduce the Normalized Total Variation (NTV), a divergence based on the propensity score summarizing the overlap between both populations (Appendix A.6).

Results: factors driving good model selection

The R-risk is the best metric. Figure 3 shows the agreement between the ideal ranking of outcome models given the oracle τ-risk and the different feasible causal metrics. We measure this agreement with relative[3] Kendall tau κ (eq. 19) [66]. Given the importance of overlap in how well metrics approximate the oracle τ-risk, we separate strong and weak overlap.

Among all metrics, the classical mean squared error (ie. factual μ-risk) is worse and reweighting it with propensity score (μ-risk$_{IPW}$) does not bring much improvements. The R-risk, which includes a model of mean outcome and propensity scores, leads to the best performances. Interestingly, the U-risk, which uses the same nuisances, deteriorates in weak overlap, probably due to variance inflation when dividing by extreme propensity scores.

Beyond rankings, the differences in terms of absolute ability to select the best model are large: The R-risk selects a model with a τ-risk only 1% higher than the best possible candidate for strong overlap on Caussim, but selecting with the μ-risk or μ-risk$_{IPW}$ –as per machine-learning practice– leads to 10% excess risk and using τ-risk$_{IPW}$ –as in some causal-inference methods [67, 68]– leads to 100% excess risk (Figure 15). Across datasets, the R-risk consistently decreases the risk compared to the μ-risk: from 0.1% to 1% on ACIC2016, 1% from to 20% on ACIC2018, and 0.05% from to 1% on Twins.

Model selection is harder for low population overlap. Model selection for causal inference becomes more and more difficult with increasingly different treated and control populations (Figure 4). The absolute Kendall's coefficient correlation with τ-risk drops from 0.9 (excellent agreement with oracle selection) to 0.6 on both Caussim and ACIC 2018 (14).

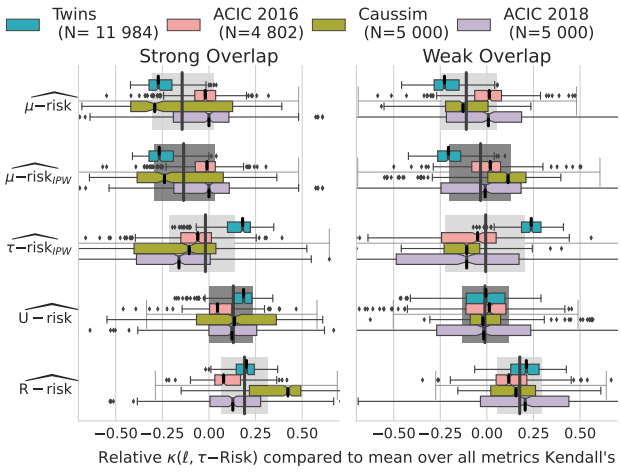

Figure 3. The R-risk is the best metric: Relative Kendall's τ agreement with τ-risk. Strong and Weak overlap correspond to the first and last tertiles of the overlap distribution measured with Normalized Total Variation eq. 16. A.7 presents the same results by adding semi-oracle risks in Figure 13, measured with absolute Kendall's in Figure 14 and with τ−risk gains in Figure 15. Table 4 gives median and IQR of the relative Kendall.

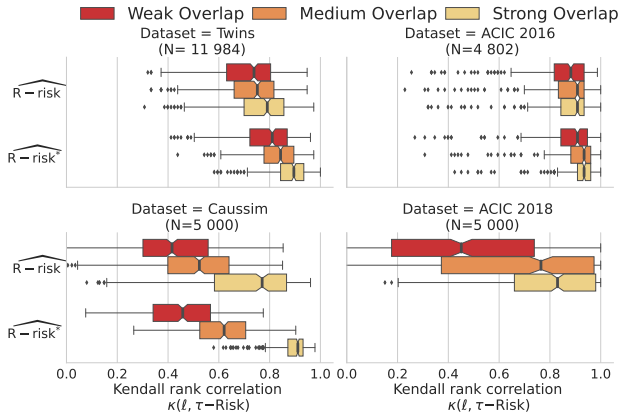

Figure 4. Model selection is harder for low population overlap: Kendall's τ agreement with τ-risk. Strong, medium and Weak overlap are the tertiles of the overlap measured with NTV eq. 16. Supplementary materials presents results for all metrics in Figure 17 in absolute Kendall's and continuous overlap values in Figure 14.

Nuisances can be estimated on the same data as outcome models. Using the train set $\mathcal{T}$ both to fit the candidate estimator and the nuisance estimates is a form of double dipping which can lead errors in nuisances correlated to that of outcome models [42]. In theory, these correlations can bias model selection and, strictly speaking, push to split out a third separated data set –a "nuisance set"– to fit the nuisance models. The drawback is that it depletes the data available for model estimation and selection. However, Figure 5 shows no substantial difference between a procedure with a separated nuisance set and the simpler shared nuisance-candidate set procedure.

Empirically, the best split is 90 %/10 %: using 90 % of the data to estimate both the nuisances and candidates, then computing the risks on the remaining test set for model selection (experiments in Appendix A.8).

Stacked models are good overall estimators of nuisances. Stacked nuisances estimators (boosting and linear) lead to feasible metrics with close performances to the oracles ones: the corresponding estimators recover well-enough the true nuisances. One may wonder if simpler models for the nuisance could be useful, in particular

2 Scikit-learn regressor, HistGradientBoostingRegressor, and classifier, HistGradientBoostingClassifier.

3 To remove the variance across datasets (some datasets lead to easier model selection than others), we report values for one metric relative to the mean of all metrics for a given dataset instance: Relative $\kappa(\ell, \tau\text{−risk}) = \kappa(\ell, \tau\text{−risk}) - mean_{\ell}\,(\kappa(\ell, \tau\text{−risk}))$

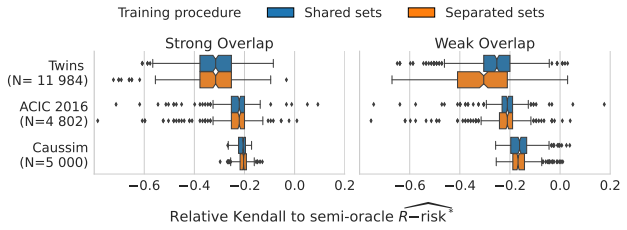

Figure 5. Nuisances can be estimated on the same data as outcome models: Results for the R-risk are similar between the shared nuisances/candidate set and the separated nuisances set procedures. Figure 16 details results for all metrics.

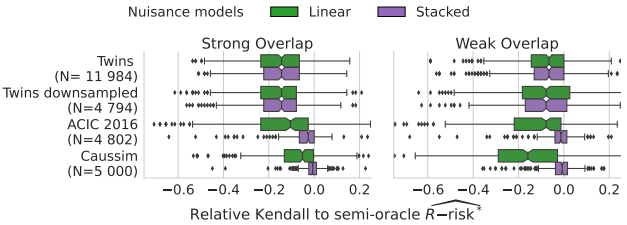

Figure 6. Stacked models are good overall estimators of the nuisances: Results are shown only for the R-risk; Figure 18 details every metrics. For Twins, where the true propensity model is linear, stacked and linear estimations of the nuisances performs equivalently, even for a downsampled version (N=4,794).

in data-poor settings or when the true models are linear. Figure 6 compares causal model selection estimating nuisances with stacked estimators or linear model. It comprises the Twins data, where the true propensity model is linear, and a downsampled version of this data, to study a situation favorable to linear models. In these settings, stacked and linear estimations of the nuisances performs equivalently. Detailed analysis (Figure 19) confirms that using adaptive models –as built by stacking linear models and gradient-boosted trees– suffices to estimate nuisance.

Discussion and conclusion

Nuisance models: more gain than pain. Predictive models are increasingly used to reason about treatment effects, for instance in precision medicine to drive individualized decision. Our results highlight that they should be selected, validated, and tuned using different procedures and error measures than those classically used to assess prediction. Rather, selecting the best outcome model according to the R-risk (eq. Definition 5) leads to more valid causal estimates. Estimating the R-risk requires a more complex procedure than standard cross-validation used *e.g.*in machine learning: it involves fitting nuisance models necessary for model evaluation. Our results show that these can be learned on the same set of data as the outcome models evaluated. The nuisance models must be well estimated (Figure 6). Our results show that using for nuisance models a flexible stacking-based family of estimator suffices for good model selection. To select propensity score models, we used the Brier score, minimized by the true individual probability. An easy mistake is to use calibration errors popular in machine learning [69, 70, 71, 72] as these select not for the individual posterior probability but for an aggregate error rate [73].

More R-risk to select models driving decisions. Increasingly complex prediction models integrating richer medical data have flourished because their predictions can be easily demonstrated and validated on left-out data. But using them to underpin a decision on whether to treat or not requires more careful validation, using a metric accounting for the putative intervention, the R-risk. The R-risk brings a sizeable benefit to select the most adequate model, even when model development is based on treated and untreated population with little differences, as in RCTs. To facilitate better model selection, we provide Python code[4]. This model-selection procedure puts no constraints on the models used to build predictive models: it opens the door to evaluating a wide range of models, from gradient boosting to convolutional neutral, or language models.
